Abstract

The development of morphological traits occurs through the collective action of networks of genes connected at the level of gene expression. As any node in a network may be a target of evolutionary change, the recurrent targeting of the same node would indicate that the path of evolution is biased for the relevant trait and network. Although examples of parallel evolution have implicated recurrent modification of the same gene and cis-regulatory element (CRE), little is known about the mutational and molecular paths of parallel CRE evolution. In *Drosophila melanogaster* fruit flies, the *Bric-À-brac* (*Bab*) transcription factors control the development of a suite of sexually dimorphic traits on the posterior abdomen. Female-specific *Bab* expression is regulated by the dimorphic element, a CRE that possesses direct inputs from body plan (*ABD-B*) and sex-determination (*DSX*) transcription factors. Here, we find that the recurrent evolutionary modification of this CRE underlies both intraspecific and interspecific variation in female pigmentation in the *melanogaster* species group. By reconstructing the sequence and regulatory activity of the ancestral *Drosophila melanogaster* dimorphic element, we demonstrate that a handful of mutations were sufficient to create independent CRE alleles with differing activities. Moreover, intraspecific and interspecific dimorphic element evolution proceeded with little to no alterations to the known body plan and sex-determination regulatory linkages. Collectively, our findings represent an example where the paths of evolution appear biased to a specific CRE, and drastic changes in function were accompanied by deep conservation of key regulatory linkages.
